## Abstract

1  
2 Light leaf spot, caused by the ascomycete *Pyrenopeziza brassicae* Sutton &  
3 Rawlinson, is an established disease of Brassicaceae in the United Kingdom (UK),  
4 and continental Europe, the European Union (EU), the United Kingdom (UK), and  
5 Oceania (OC, including New Zealand and Australia). The disease was reported in  
6 North America (NA) for the first time in 2014 on *Brassica* spp. in the Willamette  
7 Valley of western Oregon, followed by detection in *Brassica juncea* cover crops and  
8 on *B. rapa* weeds in northwestern Washington in 2016. Preliminary DNA sequence  
9 data and field observations suggest that isolates of the pathogen present in NA  
10 might be distinct from those in the UK, continental Europe, the EU, UK, and OC.  
11 Comparisons of isolates from these regions genetically (multilocus sequence  
12 analysis, *MAT* gene sequences, and rep-PCR DNA fingerprinting), pathogenically (*B.*  
13 *rapa* inoculation studies), biologically (sexual compatibility), and morphologically  
14 (colony and conidial morphology) demonstrated ~~that there are two sexually-~~  
15 ~~incompatible genetically distinct~~ evolutionary lineages. Lineage 1 comprised isolates  
16 from the UK, continental Europe, EU, UK, and OC ~~isolates~~, and included the *P.*  
17 *brassicae* type specimen. Lineage 2 contained the NA isolates associated with  
18 recent disease outbreaks in the Pacific Northwest region of the USA. Symptoms  
19 caused by isolates of the two lineages on *B. rapa* and *B. juncea* differed, so 'chlorotic  
20 leaf spot' is proposed for the disease caused by lineage 2 isolates of *P. brassicae*.  
21 Isolates of the two lineages differed in genetic diversity as well as sensitivity to the  
22 fungicides carbendazim and prothioconazole.

## Introduction

1 Light leaf spot, caused by the ascomycete *Pyrenopeziza brassicae* Sutton &  
2 Rawlinson (anamorph *Cylindrosporium concentricum* Grev.), is an economically  
3 important disease of many Brassicaceae [Rawlinson *et al.* 1978; Centre for  
4 Agriculture and Biosciences International (CABI) 2015]. The pathogen is widespread  
5 geographically, having been reported in Asia (Japan and the Philippines), continental  
6 Europe the European Union (EU, including France, Germany, and Poland), the  
7 United Kingdom (UK), and Oceania (OC, including Australia and New Zealand).  
8 Light leaf spot is one of the most important diseases of *Brassica napus* (oilseed  
9 rape) in the UK and northern parts of continental Europe (Boys *et al.* 2007).  
10 However, excluding a single unconfirmed record from Oregon State in 1998  
11 (Phytosanitary Alert System 2015), light leaf spot had not previously been  
12 documented in North America (NA). The disease was first found on *Brassica juncea*,  
13 *B. napus*, and *Brassica rapa* in six counties in the Willamette Valley of western  
14 Oregon in 2014 (Ocamb *et al.* 2015), and subsequently has been detected in  
15 additional counties on multiple Brassicaceae genera and species in western Oregon  
16 (Claassen 2016). In 2016, light leaf spot was detected in *B. juncea* cover crops and  
17 on *B. rapa* weeds (birdrape mustard) in three counties in northwestern Washington  
18 (Carmody *et al.* 2016). Isolates of *P. brassicae* obtained off diverse Brassicaceae  
19 genera and species in Oregon and Washington were confirmed to be pathogenic on  
20 *B. juncea*, *B. napus*, *B. oleracea*, and *B. rapa* (Carmody 2017; Claassen 2016). Light  
21 leaf spot can cause reduced photosynthesis, stunting, pod shatter (for seed crops),  
22 and associated declines in yield (Claassen 2016; Karandeni Dewage *et al.* 2018).  
23 Thus, the relatively recent appearance of light leaf spot in Oregon and Washington  
24 could pose a threat to production of economically important crops of the many  
25 diverse types of Brassicaceae grown in the Pacific Northwest USA, including *B.*

1 *napus*, *B. oleracea*, and *B. rapa* crops (Inglis *et al.* 2013; Phytosanitary Alert System  
2 2015).

3 Light leaf spot appears to have undergone very recent, rapid, and invasive  
4 spread in the US Pacific Northwest given that: i) the disease was not observed in  
5 surveys of *Brassica* and *Raphanus* crops in Oregon from 2010 to 2013 (Ocamb  
6 2014), ii) light leaf spot was first reported in Oregon in 2014 (Ocamb *et al.* 2015) and  
7 is now widespread across parts of western Oregon (Claassen 2016), and iii) the  
8 disease was found in three counties in northwestern Washington in 2016 (Carmody  
9 2017). The origins of the isolates associated with these recent outbreaks in NA are  
10 not yet known. As is the case with many newly emerging plant diseases, the  
11 outbreaks in NA might have resulted from introduction of the pathogen (Anderson *et*  
12 *al.* 2004) into the Pacific Northwest US, perhaps via infected planting material, given  
13 evidence for the seedborne and seed transmitted nature of the fungus (Carmody  
14 2017; Carmody & du Toit 2017). If the pathogen was introduced recently to NA,  
15 candidate regions of origin of the pathogen include areas where the disease has  
16 long been reported, such as [the UK, continental Europe, and the EU, OC, and UK](#)  
17 (CABI 2015; Rawlinson *et al.* 1978]. However, a preliminary comparison of  
18 sequences of the internal transcribed spacer (ITS) region of ribosomal DNA (rDNA)  
19 of five NA isolates suggested that they were distinct genetically from [European and](#)  
20 [UK EU](#)-isolates as the sequences only had 95% nucleotide similarity (Carmody  
21 2017). The *β-tubulin* gene sequences of the same NA isolates had 98% nucleotide  
22 similarity to isolates of *P. brassicae* from the [EU and UK and continental Europe](#)  
23 (Carmody 2017). This initial evidence that the light leaf spot pathogen isolates in NA  
24 might be distinct genetically from those [from continental Europe in the EU and the](#)

1 UK highlighted the need to assess the pathogen on a larger temporal and spatial  
2 scale.

3         Dispersal of *P. brassicae* inoculum during the growing season in areas where  
4 this pathogen is established is considered mainly to be by short distance splash-  
5 dispersal of asexual conidia, with multiple (polycyclic) rounds of host infection (Gilles  
6 *et al.* 2001; Karandeni Dewage *et al.* 2018). In addition, wind-dispersed ascospores  
7 are released into the air forcibly from apothecia that form on infected host debris,  
8 typically in late summer and autumn (Cheah *et al.* 1982; Gilles *et al.* 2001).  
9 Ascospores are thought to act as primary sources of inoculum that initiate light leaf  
10 spot outbreaks in ~~the UK and continental Europe the EU and UK~~ (Karolewski *et al.*  
11 2012). Sexual reproduction by *P. brassicae* has long been documented in the UK  
12 ~~and continental Europe EU and UK~~ (Lacey *et al.* 1987) as well as OC (Cheah *et al.*  
13 1982). Isolates of complementary *MAT1-1* and *MAT1-2* types are required for sexual  
14 reproduction (Foster *et al.* 2002; Ilott *et al.* 1984). Apothecia have not been found in  
15 association with outbreaks of light leaf spot in NA, and it is not known whether a  
16 sexual cycle occurs in NA. However, this information is important to underpin  
17 management strategies for light leaf spot as populations with both sexual and  
18 asexual reproduction tend to have greater evolutionary potential than those that are  
19 exclusively asexual (McDonald & Linde 2002). Such populations also present a  
20 greater risk of failures in disease management strategies, e.g., if strains of the  
21 pathogen overcome host resistance genes (Boys *et al.* 2007) or develop resistance  
22 to fungicides commonly used in brassica crops, as has occurred in the UK and  
23 ~~continental Europe the EU and UK~~ (Carter *et al.* 2013; 2014).

24         Effective management of light leaf spot in areas where this disease has  
25 established has necessitated the integration of planting cultivars with resistance to

1 the disease, applying fungicides with efficacy against the pathogen, and  
2 implementing cultural practices such as incorporation of infected crop residues into  
3 the soil and/or crop rotation (Karandeni Dewage *et al.* 2018). Host resistance alone  
4 has been insufficient to control economically damaging outbreaks of light leaf spot in  
5 *B. napus* crops as there are no fully resistant commercial cultivars available currently  
6 (Boys *et al.* 2007; 2012). Thus, management of this disease in conventional crops  
7 has depended on applications of fungicides, including methyl benzimidazole  
8 carbamates [MBCs, Fungicide Resistance Action Committee (FRAC) Group 1] and  
9 azoles [sterol 14 $\alpha$ -demethylation inhibitors (DMIs), FRAC Group 3] (Carter *et al.*  
10 2013; 2014). However, reduced sensitivity to these fungicides has been reported for  
11 some UK and continental European isolates EU and UK isolates of *P. brassicae*,  
12 and the molecular mechanisms of resistance have been characterized (Carter *et al.*  
13 2013; 2014). Genotypic and phenotypic data on fungicide sensitivity of NA isolates of  
14 the light leaf spot pathogen are needed to monitor the current and future potential  
15 efficacy of fungicide applications for control of this disease in NA.

16 Given the increasing losses associated with light leaf spot in areas where this  
17 disease is well established, and preliminary evidence of genetic differentiation of  
18 isolates of the fungus causing this disease in NA from isolates in the the UK and  
19 continental Europe EU and UK, there is a need to characterize these pathogen  
20 populations. The primary objective of this study was to compare isolates of the light  
21 leaf spot pathogen from regions where *P. brassicae* has long been established, i.e.,  
22 the the UK and continental Europe and OC EU, OC, and UK (Majer *et al.* 1998), with  
23 isolates from NA, where light leaf spot was found recently. The isolates evaluated in  
24 this study were obtained from a range of Brassicaceae genera and species, and  
25 compared using the consolidated species concept (CSC) by combining

1 morphological, ecological, biological, and genetic (phylogenetic) data (Crous *et al.*  
2 2015).

#### Materials and methods

5 ***Pyrenopeziza* isolates and herbarium specimens.** Details of the light leaf

6 spot fungal isolates used in this study, including isolates and herbarium specimens

7 of infected leaves submitted to the Westerdijk Fungal Biodiversity Institute in the

8 Netherlands, isolates deposited in the CABI [International Mycological Institute (IMI)]

9 collection in the UK, and GenBank accession numbers for fungal DNA sequences,

10 are listed in Table 1. [The GenBank accession numbers listed in Table 1 were all](#)

11 [generated as part of this study.](#) For each [UK, continental Europe, or OC EU, OC, or](#)

12 [UK](#) isolate, infected leaves [from a collection at Rothamsted Research](#) were

13 examined with a stereomicroscope, and a single pustule was placed into a drop of

14 sterilized distilled water (SDW) using a sterilized needle. The conidial suspension

15 was spread onto a plate of 3% malt extract agar using a sterilized disposable loop,

16 and incubated at 15°C for 10 days. Single colonies were then used to establish

17 single-spore cultures. For each NA isolate, small pieces (up to 5 mm<sup>2</sup>) of

18 symptomatic leaf and stem tissue were surface-sterilized in 1.2% NaOCl for up to 2

19 minutes, and rinsed three times in SDW; or sterilized in 70% ethyl alcohol for 5 secs,

20 dried on sterilized blotter paper, and plated onto clarified V8 (cV8) agar amended

21 with chloramphenicol (100 mg/litre) (Carmody 2017). The leaf pieces were incubated

22 under a day/night cycle at 15°C with cool white fluorescent light and near-ultraviolet

23 (NUV) light for 8 h/day, and 10°C in the dark for 16 h/day. The cultures were used to

24 generate single-spore isolates by streaking a spore suspension of each isolate onto

25 water agar (WA) and picking individual colonies. A single Australian isolate of *P.*

1 *brassicae* (CBS 157.35) was obtained from the Westerdijk Fungal Biodiversity  
2 Institute. Single-spore [isolatescultures](#) were maintained [in the at Rothamsted](#)  
3 [Research \(UK\) culture collection](#) in 88% glycerol suspensions at -80°C [in the](#)  
4 [Rothamsted Research \(UK\) culture collection](#), and at the Washington State  
5 University (WSU) Mount Vernon Northwestern Washington Research & Extension  
6 Center (NWREC) on dried, colonized filter disks stored at -20°C with desiccant.  
7 Additional herbarium specimens were obtained from the CABI collection (IMI81823,  
8 IMI204290, and IMI 233715-7) and the Westerdijk Fungal Biodiversity Institute  
9 (CBS157.35).

10 **DNA extraction.** At Rothamsted Research, genomic DNA was extracted from  
11 lyophilized mycelium of each isolate using a MasterPure Yeast DNA Purification kit  
12 (Epicentre). DNA concentration was then quantified using a Nanodrop  
13 photospectrometre, and diluted to the required concentration using PCR grade  
14 water. At the WSU Mount Vernon NWREC, genomic DNA was extracted from  
15 mycelium harvested from potato dextrose broth liquid cultures using a DNeasy Plant  
16 Mini Kit (Qiagen). DNA concentration was then quantified using a Qubit Fluorometer,  
17 and diluted to the required concentration using PCR grade water.

18 **Genus confirmation and multilocus sequence analysis.** To verify identity  
19 of the genus of the NA isolates as *Pyrenopeziza*, phylogenetic analyses were  
20 completed for the partial ITS rDNA of 30 isolates of the light leaf spot pathogen (12  
21 [from NA isolates, and 138 from the UK, 4 from continental European EU, and 2 from](#)  
22 [OC, and UK isolates](#)) along with ITS rDNA sequences of isolates of 57 related fungi,  
23 including sequences available in GenBank for seven other *Pyrenopeziza* species (*P.*  
24 *ebuli*, *P. eryngii*, *P. petiolaris*, *P. plicata*, *P. revincta*, *P. subplicata*, and *P.*  
25 *velebitica*), nine *Cadophora* species, two *Graphium* species, *Hormodendrum pyri*,

1 two *Hymenoscyphus* species, *Leptodontidium orchidicola*, five *Mollisia* species, three  
2 *Oculimacula* species, four *Phialophora* species, two *Phialocephala* species, two  
3 *Rhynchosporium* species, and *Tapesia cinerella* (Table 1, Supplementary Table 1,  
4 Figure 13A). The ITS rDNA sequence obtained from a genome of *Botryosphaeria*  
5 *dothidea* served as the outgroup (Supplementary Table 1). In addition, the  $\beta$ -*tubulin*  
6 and *translation elongation factor 1- $\alpha$*  (*TEF1- $\alpha$* ) genes were amplified from the same  
7 30 isolates of *P. brassicae* isolates from the UK and continental Europe EU, OC, UK,  
8 and NA as well as from closely related fungi (Table 1 and Supplementary Table 1),  
9 for completing individual phylogenetic analyses of each DNA region as well as  
10 multilocus sequence analysis (MLSA) of concatenated sequences of the three DNA  
11 regions. Relevant sequences from *B. dothidea* served as outgroups for these  
12 analyses (Crous *et al.* 2003) (Supplementary Table 1; Figure 13B, 13C, and 13D).

13 Primers used for the amplification of various DNA sequences are detailed in  
14 Table 2. The ITS rDNA was amplified as described by Bakkeren *et al.* (2000) in a  
15 total reaction volume of 30  $\mu$ l that included 1x buffer (Invitrogen Life Technologies),  
16 1.5 mM MgCl<sub>2</sub>, 0.20 mM of each dNTP, 0.4 mM of each primer, 1.5 Units of *Taq*  
17 DNA polymerase (Invitrogen Life Technologies), and 2  $\mu$ l of genomic DNA. The  $\beta$ -  
18 *tubulin* gene was amplified as detailed by Einax & Voigt (2003) in a total reaction  
19 volume of 25  $\mu$ l, including 1x buffer, 1.5 mM MgCl<sub>2</sub>, 0.4 mM of each dNTP, 0.24 mM  
20 of each primer, 1.25 Units of *Taq* DNA polymerase, and 1  $\mu$ l of genomic DNA. The  
21 *TEF1- $\alpha$*  gene was amplified using the protocol described by Taşkin *et al.* (2010) in a  
22 total reaction volume of 20  $\mu$ l, which included 1x buffer, 1.5 mM MgCl<sub>2</sub>, 0.15 mM of  
23 each dNTP, 0.15 mM of each primer, 1 Unit of *Taq* DNA polymerase, and 2  $\mu$ l of  
24 genomic DNA. PCR reactions were done in a Thermohybrid PCR Express  
25 Thermocycler (ThermoFisher Scientific) using the following cycles:

1 94°C for 3 min; 31 cycles of 92°C for 45 s, 60°C for 45 s, and 72°C for 1 min;  
2 and 72°C for 10 min for ITS rDNA amplification;  
3 94°C for 3 min; 35 cycles of 92°C for 45 s, 55°C for 45 s, 72°C for 1 min; and  
4 72°C for 10 min for *β-tubulin* amplification; and  
5 95°C for 2 min; 35 cycles of 95°C for 15 s, 58°C for 45 s, and 72°C for 45 s;  
6 and 72°C for 5 min for *TEF1-α* amplification.

7 After running the amplified products on 1.5% agarose gels to confirm single bands,  
8 PCR products were cleaned using an ExoSAP-IT kit (ThermoFisher Scientific) and  
9 sent to Elim Biopharmaceuticals, Inc. for bi-directional sequencing. Primers used for  
10 PCR amplification were also used in the sequencing reactions (Table 2). The DNA  
11 sequences were processed using MEGA 7 (Kumar *et al.* 2016), and deposited in  
12 GenBank (Table 1).

13 **Phylogenetic analyses.** Partial sequences from the ITS rDNA region, *β-*  
14 *tubulin* gene, and *TEF1-α* gene, along with concatenated sequences of the three  
15 regions were aligned using ClustalW in Geneious 10.2.3 (Biomatters Ltd.), and  
16 trimmed to equal lengths of 485 nt for the ITS rDNA, 662 nt for *β-tubulin*, and 535 nt  
17 for *TEF1-α*. Model selection was done using jModelTest 2.1.1.0 (Darriba *et al.* 2012).

18 Bayesian analyses were completed using MrBayes 3.2.6 (x64). The Monte  
19 Carlo Markov Chain (MCMC) analyses for individual genes and the concatenated  
20 alignment were run for 10<sup>6</sup> generations, with the first 25% discarded in the initial  
21 burn-in and chains sub-sampled every 500 generations. The best-fit model used for  
22 each analysis was GTR+I+G, except for the *TEF1-α gene* for which the GTR+G  
23 model was selected. The MCMC output was inspected to confirm acceptable burn-in  
24 length and chain convergence (stationarity), and the consensus trees were viewed in  
25 TreeView V.1.6.6. The phylogenetic trees for individual DNA sequences and the

1 concatenated sequences (Figure 13A to 13D) were submitted to Treebase  
2 (TB2:S24431). In addition, maximum likelihood analyses were completed with the  
3 same CLUSTALW alignments as for the Bayesian analyses, using the PHMYL  
4 (3.3.20180621) plugin in Geneious. For all analyses, the GTR model was selected  
5 and bootstrapping was based on 100 replications. The consensus trees were rooted  
6 with *B. dothidea* sequences and viewed using TreeView,

7 **Mating type screening, distribution, and phylogeny.** Sequences of the  
8 Phylogenetic analyses of the MAT1-1 and MAT1-2 genes sequences also were  
9 amplified from 40 isolates of *P. brassicae* (Table 1) to enable phylogenetic analyses  
10 of these mating type genes completed. Sequences were obtained from a selection  
11 of the isolates (Table 1) using the Foster *et al.* (2002) multiplex PCR assay.

12 Reactions were done in 20 µl volumes, each containing 10 µl MegaMix-Blue  
13 (Microzone); 1 µl each of primers PbM-1-3, PbM-2, and the reverse primer Mt3  
14 (Table 2), with each primer at a final concentration of 0.5 µM; 5 µl PCR grade water;  
15 and 2 µl unquantified DNA extract. Amplicons were resolved on a 2% agarose gel  
16 and sent to MWG Eurofins for sequencing with primer Mt3.

17 **Rep-PCR DNA fingerprinting.** Rep-PCR fingerprinting of a selection of nine  
18 isolates of the light leaf spot pathogen from NA and 10 isolates from the UK,  
19 continental Europe, and OC (Table 1, Figure 4) was done using the protocols and  
20 primers described by Versalovic *et al.* (1994). Each reaction was completed in a 20  
21 µl volume containing 10 µl JumpStart REDTaq ReadyMix (Sigma Aldrich), 2 to 4 µl  
22 of each primer (see details below), 6 µl PCR grade water, and 2 µl DNA (20 ng total  
23 per reaction). Three variants of rep-PCR fingerprinting were done: 1) BOX PCR for  
24 which each reaction included 4 µl of primer BOXAIR at a ~~final~~ 1 µM final  
25 concentration; 2) ERIC PCR for which each reaction included 2 µl each of primers

1 ERIC1R/ERIC2 with each primer at a 0.5  $\mu\text{M}$  final concentration; and 3) GTG<sup>5</sup> PCR  
2 for which each reaction included 4  $\mu\text{l}$  of primer GTG<sup>5</sup> at a 1  $\mu\text{M}$  final concentration.  
3 Reaction conditions were: 96°C for 2 min; 35 cycles of 94°C for 30 s, 52°C for 1 min,  
4 and 65°C for 5 min; and a final step at 65°C for 8 min. PCR products (8  $\mu\text{l}$ ) were  
5 subsequently visualized on a 2% agarose gel (110 volts for 3 h) with ethidium  
6 bromide.

7 **Pathogenicity of NA isolates on brassicas.** *B. rapa* turnip plants (cv.  
8 Hakurei; Osborne International Seed Co.) and *B. juncea* mustard plants (cv. Caliente  
9 199; High Performance Seeds, Inc.) were used to test pathogenicity of 17 NA  
10 isolates of the light leaf spot pathogen (Table 1). Seed of each cv. were sown in  
11 RediEarth Seedling Starter Mix (SunGro) in 72-cell flats (2 seed/cell, with each cell  
12 3.8 cm diameter x 5.7 cm deep) in a greenhouse at 20  $\pm$  3°C by day and 15  $\pm$  3°C by  
13 night with supplemental lighting for 12 h/day, at the WSU Mount Vernon NWREC.  
14 Three weeks later, the seedlings were transplanted into Sunshine Mix #1 (SunGro)  
15 in 15-cm diameter plastic pots. Plants were inoculated with the light leaf spot isolates  
16 six weeks after transplanting. The day prior to inoculation, the plants were incubated  
17 overnight in polyethylene bags under a greenhouse bench that was covered with two  
18 layers of Remay cloth for shading to prevent plants overheating in the bags.

19 Based on limited availability of space, the 17 NA isolates were tested for  
20 pathogenicity in groups over a total of three trials (four isolates in trial 1, 2 isolates in  
21 trial 2, and 11 isolates in trial 3) at the WSU Mount Vernon NWREC (Table 1). A  
22 conidial suspension was prepared for each isolate using 6- to 8-week-old colonized  
23 plates of V8 agar medium by adding 20 ml SDW onto the surface of each plate and  
24 gently rubbing the surface of the culture using a sterilized, bent glass rod. Each  
25 spore suspension was filtered through two layers of cheesecloth, and the

1 concentration adjusted to  $1 \times 10^6$  conidia/ml, to which Tween 20 was added (0.01%).  
2 Four replicate plants each of *B. rapa* and *B. juncea* were inoculated with either: 1) a  
3 tester NA isolate, 2) a NA isolate previously demonstrated to be pathogenic on  
4 brassicas (Cyc001, the positive control treatment), or 3) SDW (negative control  
5 treatment). Each treatment was applied using an atomizer (Rescende Model 175,  
6 Badger Air-Brush Co.) until the leaves were coated with fine droplets. Plants were  
7 then placed back in the polyethylene bags under greenhouse benches covered in  
8 Remay for 48 h to promote fungal infection, removed from the bags, and laid out on  
9 greenhouse benches in a randomized complete block (RCB) design.

10 Each inoculation trial was set up as a two-factor factorial treatment design  
11 consisting of the two *Brassica* species (*B. juncea* and *B. rapa*) inoculated with the  
12 test isolates and control treatments. Three leaves of each plant were rated 14 and 21  
13 days after inoculation (dai) for the type of symptoms (chlorosis and/or necrosis) and  
14 the percentage of leaf area with symptoms. Those pPlants on which veinal browning  
15 was the primary symptom were rated as having 1% severity of symptoms. The mean  
16 severity ratings of three leaves/plant for each replication of each treatment  
17 combination were subjected to analyses of variance (ANOVA), with replication  
18 treated as a random effect, and plant species and isolates as fixed effects. Data from  
19 the SDW-treated control plants were excluded from the ANOVA because symptoms  
20 did not develop on those plants. Assumptions of normality and equal variance were  
21 tested. Treatment means were compared using Fisher's protected least significant  
22 difference (LSD) at  $P < 0.05$ . Lesions that developed were examined microscopically  
23 21 dai to confirm the presence of acervuli and conidia of the pathogen. Isolations  
24 from lesions caused by each of the 17 isolates were completed as described above

1 for the original light leaf spot samples collected in NA, and ITS rDNA and *β-tubulin*  
2 sequences were generated from the re-isolates as described above.

3 **Comparative symptomology caused by isolates from the UK and**  
4 **continental Europe EU and UK vs. isolates from NA.** To compare symptoms  
5 **ology** caused by isolates from the UK and continental Europe vs. EU and UK vs.  
6 isolates from NA isolates, *B. rapa* turnip seedlings (cv. Hakurei) were grown in a  
7 greenhouse as described above. Four replicate plants were inoculated with each of  
8 11 light leaf spot isolates (10 from the UK and continental Europe EU and UK isolates  
9 as well as NA isolate Cyc001) or SDW as described above, with the plants laid out in  
10 a RCB design. By 14 dai, plants inoculated with the NA isolates displayed very  
11 different symptoms from those inoculated with UK and continental Europe EU and  
12 UK isolates (see Results) and, thus, had to be rated differently. Plants inoculated  
13 with the NA isolate were assessed for percentage of leaf area with symptoms by  
14 rating three leaves/plant, as described above. Plants inoculated with UK or  
15 continental Europe EU or UK isolates were scored for the presence or absence of  
16 circular patches of white conidiomata on three leaves/plant at 28 dai (Figure 2A and  
17 2B4). The number of inoculated leaves that were chlorotic, necrotic (senesced), or  
18 had patches of white conidiomata were rated 21 and 28 dai (based on the total  
19 number of leaves present at the time of inoculation). Re-isolations of fungi were done  
20 from leaf spot lesions for the NA isolate, from sections of leaves with white  
21 conidiomata for UK and continental Europe the EU and UK isolates, or from  
22 asymptomatic tissue for control plants treated with SDW, as described previously. In  
23 addition, leaf sections were examined microscopically for *Pyrenopeziza acervuli* and  
24 conidia.

1 Leaf rating data were subjected to ANOVA for the number of inoculated  
2 leaves with white conidiomata/plant, the number of inoculated necrotic leaves/plant,  
3 and the number of inoculated chlorotic leaves/plant 28 dai. Replications were treated  
4 as a random effect and isolates as a fixed effect in the model. Control plants treated  
5 with SDW were excluded from the analyses because symptoms did not develop on  
6 those plants. Plants inoculated with the NA isolate were excluded from the ANOVA  
7 for the number of inoculated leaves with white conidiomata, as none was observed  
8 on those plants. Disease severity ratings 28 dai were used for ANOVAs because the  
9 number of necrotic leaves was much greater than at 21 dai. Assumptions of  
10 normality and equal variance were tested. Assumptions for parametric analysis were  
11 met for the number of inoculated leaves with white conidiomata and the number of  
12 inoculated leaves that turned necrotic, while data for the number of inoculated leaves  
13 that turned chlorotic had to be analyzed using Friedman's non-parametric rank test.  
14 Treatment means were compared using Fisher's protected LSD at  $P < 0.05$ . The  
15 pathogenicity test was repeated.

16 **Sexual compatibility testing.** Twenty light leaf spot isolates, 10 from NA  
17 (five *MAT1-1* and five *MAT1-2*) and 10 from the [UK or continental Europe EU or UK](#)  
18 (five *MAT1-1* and five *MAT1-2*), were grown from -80°C glycerol stocks onto 3%  
19 MEA plates, incubated in the dark at 18°C, and used to attempt sexual crosses  
20 (Tables 1 and 3). After six weeks, 1 mL of SDW water was added to the surface of  
21 each stock plate and the colonies agitated using a sterilized bent glass rod. The  
22 conidial suspension was filtered through a double layer of sterilized cheesecloth and  
23 adjusted to  $1 \times 10^6$  conidia/ml. A 40 µl aliquot of conidial suspension from each of the  
24 two isolates used for each attempted sexual cross was placed onto a plate of 3%  
25 MEA and the two aliquots spread across the agar surface using a sterilized bent

1 glass rod. Plates were sealed with Parafilm and incubated for a further 9 weeks in  
2 the dark at 18°C, after which plates were examined microscopically at weekly  
3 intervals for the presence or absence of apothecial initials, mature apothecia, and  
4 asci with ascospores (the latter determined microscopically from thin apothecial  
5 sections examined at  $\leq 100$  x magnification). Each sexual cross was attempted using  
6 three replicate plates of MEA.

7 **Morphological comparison.** Light leaf spot isolates, ~~10~~ from NA and ~~10~~ from  
8 the ~~UK and continental Europe EU and UK~~, were compared morphologically *in vitro*  
9 and *in planta* (Table 1). For *in vitro* comparison, cultures were initiated from -80°C  
10 glycerol stocks onto three replicate 3% MEA plates for each of four ~~isolates from the~~  
11 ~~EU/UK and continental Europe compared to~~ and 10 NA isolates. ~~The~~ and the plates  
12 ~~were~~ incubated at 18°C in the dark for four months, at which time the plates were  
13 photographed. For comparison of conidial morphologies *in vitro*, 10 ~~UK and~~  
14 ~~continental Europe EU and UK~~ isolates, and eight NA isolates (all isolates listed in  
15 Table 3 excluding two of the 10 NA isolates which sporulated poorly) were grown for  
16 six weeks on 3% MEA as detailed above, after which conidia were harvested and  
17 examined microscopically. Conidial shape was examined for each isolate, and the  
18 length and diameter of 25 conidia/isolate were measured using a digital CCD camera  
19 (Hamamatsu C8484 05G01) and *HCImage* software (Hamamatsu Photonics K.K.).  
20 Conidial dimensions for the ~~UK and continental European EU and UK~~ isolates were  
21 compared with those of the NA isolates using Student's *t* test (Graphpad Software).

22 For examination of conidial morphology *in planta*, conidia were washed from  
23 inoculated, symptomatic leaves of *B. rapa* turnip (cv. Hakurei) plants that had been  
24 inoculated 28 days previously with 20 isolates of the light leaf spot pathogen (10  
25 ~~continental Europe U~~ and UK isolates, and 10 NA isolates; Table 1). The length and

1 width, and the presence or absence of a septum were recorded for each of 60  
2 conidia per isolate. Photographs of conidia were taken with a Leica camera  
3 (DFC295, Wetzlar) and Leica Application Software Version 3.8 (Leica  
4 Microsystems). An ANOVA was used to compare conidial dimensions of UK and  
5 continental Europe EU and UK isolates with those of NA isolates (geographic  
6 location), and among isolates within the two major geographic regions. Geographic  
7 region was treated as a fixed effect and isolates as a random effect in the models.  
8 Symptomatic leaves infected with each of the 10 UK and continental Europe isolates  
9 EU or UK and the 10 NA isolates were harvested from the same plants and pressed  
10 at the time conidia were washed from the leaves. The pressed leaves were  
11 submitted to the Westerdijk Fungal Biodiversity Institute along with agar cultures of  
12 each isolate (Table 1). Live cultures of representative isolates were also deposited  
13 into the CABI (IMI) collection (Table 1).

14 **Fungicide sensitivity testing and molecular analyses.** Ten isolates of the  
15 light leaf spot pathogen, including four reference UK and continental European EU  
16 and UK isolates with different sensitivity profiles to carbendazim and  
17 prothioconazole, and six NA isolates that had not previously been tested for  
18 sensitivity to these fungicides (Tables 1 and 4), were initiated from -80°C glycerol  
19 stocks onto 3% MEA plates. After three weeks, 1 ml of SDW was added to the  
20 colony surface of each isolate and agitated using a sterilized, bent glass rod. Each  
21 conidial suspension was filtered through sterilized cheesecloth and adjusted to  $1 \times 10^5$   
22 conidia/ml. A 10  $\mu$ l droplet of conidial suspension was placed on the centre of a  
23 plate of PDA (60 mm diameter x 15 mm deep, with 10 ml of medium per plate)  
24 containing: 1) no fungicide, 2) 0.39  $\mu$ g carbendazim/ml, or 3) 1.56  $\mu$ g  
25 prothioconazole/ml. Each isolate was tested on three amended agar plates for each

1 of the three treatments. Plates were dried in a laminar flow hood for 10 min, sealed  
2 with a double layer of Parafilm, incubated for 18 days in the dark at 18°C, and  
3 examined for the presence or absence of visible fungal colonies. In addition, the  $\beta$ -  
4 *tubulin* gene sequences from 12 NA isolates (Table 1) were examined for the  
5 presence of key amino acid substitutions that have previously been correlated with  
6 resistance to MBC fungicides in some ~~EU and UK~~ isolates [from the UK and](#)  
7 [continental Europe](#) (Carter *et al.* 2013).

## 8 9 Results

10 **Genus confirmation.** Phylogenetic analysis of the ITS rDNA of 18 [UK,](#)  
11 [continental European and EU, OC, and UK](#) isolates of *P. brassicae* obtained from *B.*  
12 *napus*, *B. oleracea*, and *B. rapa* plants; 12 NA isolates obtained from *B. juncea*, *B.*  
13 *napus*, *B. rapa*, and *Raphanus* spp.; and 57 isolates of closely related fungi revealed  
14 the NA isolates to group most closely with isolates of *P. brassicae* (Figure 13A).  
15 None of the ITS rDNA sequences of the seven other *Pyrenopeziza* species or other  
16 closely related fungal genera grouped with the NA isolates. Thus, the NA isolates  
17 were confirmed to be a *Pyrenopeziza* sp. most closely related to *P. brassicae*.

18 **Multilocus sequence analyses.** Bayesian phylogenetic analyses of the ITS  
19 rDNA (Figure 13A),  $\beta$ -*tubulin* (Figure 13B), and *TEF1- $\alpha$*  sequences (Figure 13C) as  
20 well as the concatenated sequences (Figure 13D) all revealed the [UK, continental](#)  
21 [European and OC EU, OC, and UK](#) isolates of *P. brassicae* formed a genetically  
22 distinct lineage, henceforth referred to as lineage 1, from the NA isolates, henceforth  
23 referred to as lineage 2. Maximum likelihood analyses of the same sequences (ITS  
24 rDNA in Supplementary Fig 1A,  $\beta$ -*tubulin* in Supplementary Figure 1B, *TEF1- $\alpha$*   
25 sequences in Supplementary Figure 1C, and the concatenated sequences in

1 Supplementary Figure 1D) gave very similar results. Both Bayesian and maximum  
2 likelihood analyses supported two distinct lineages that were defined solely by  
3 geographic origin, with no evidence for additional grouping based on the *Brassica* or  
4 *Raphanus* species from which the isolates originated. These two lineages were more  
5 similarly related to each other than to sequences of any other related fungal genera  
6 examined for all DNA regions evaluated (Figure 13; Supplementary Figure 1). The  
7 partial ITS rDNA sequence (GenBank Accession No. MN028386) obtained from the  
8 type herbarium specimen of *P. brassicae* (IMI81823), showed this isolate grouped  
9 into lineage 1.

10 **Mating type screening, distribution, and phylogeny.** All of the light leaf  
11 spot isolates produced a single amplicon when screened with the multiplex mating  
12 type diagnostic PCR assay developed by Foster *et al.* (2002). Lineage 1 isolates  
13 produced amplified DNA fragments of either 687 bp for the *MAT1-1* isolates or 858  
14 bp for the *MAT1-2* isolates. In contrast, for lineage 2 isolates, *MAT1-1* isolates  
15 yielded a smaller, ~786 bp product, which was smaller than the 687 bp product for  
16 lineage 1 isolates, whereas *MAT1-2* isolates produced a ~858 bp fragment of similar  
17 size to that of the lineage 1 isolates. Sequence analyses revealed that the larger  
18 product size for *MAT1-1* in lineage 2 isolates was due to a 99 bp indel that coded for  
19 an additional 33 amino acids (aa) targeted by the primers (Singh & Ashby 1998); no  
20 reading frame disruption or premature stop codons were observed in the translated  
21 aa sequence.

22 Examination of mating type distributions did not reveal statistically significant  
23 deviations from a 1:1 ratio for the 33 lineage 1 isolates of *P. brassicae* (15:18 *MAT1-*  
24 *1*:*MAT1-2* isolates:  $\chi^2 = 0.273$ , 1 df,  $P = 0.6015$ ) or the 16 lineage 2 isolates (8:8  
25 *MAT1-1*:*MAT1-2* isolates:  $\chi^2 = 0$ , 1 df,  $P = 1.000$ ). Both *MAT1-1* and *MAT1-2* type

1 isolates of lineage 2 were present in each of Oregon and Washington. Inspection of  
2 sequences of the *MAT1-1-3* gene from *MAT1-1* isolates and *MAT1-2-1* gene from  
3 *MAT1-2* isolates also clearly resolved the two lineages, with 90.36% similarity for  
4 *MAT1-1* isolates and 93.24% for *MAT1-2* isolates (*data not shown*).

5 **Rep-PCR DNA fingerprinting.** All three rep-PCR variants tested (BOX, ERIC  
6 and GTG<sup>5</sup>) consistently resolved lineage 1 isolates of the light leaf spot pathogen  
7 from lineage 2 isolates (Figure 5). Evidence for high genotypic variability was also  
8 observed for the ERIC and GTG<sup>5</sup> data, with unambiguous bands scored as  
9 present/absent for each isolate (Figure 5 bands scored with arrows). Based on  
10 scoring of bands, 3 of 10 lineage 1 isolates (30%), and 7 of 9 lineage 2 isolates  
11 (78%) had unique genotypes.

12 **Pathogenicity of lineage 2 isolates on brassicas.** The 17 isolates from  
13 lineage 2 that were tested for pathogenicity on the turnip (*B. rapa* cv. Hakurei) and  
14 mustard (*B. juncea* cv. Caliente 199) plants all caused chlorotic, rapidly expanding,  
15 foliar lesions on both hosts (Figure 24C). Symptoms were not observed on SDW-  
16 treated control plants of either species. Data met assumptions for parametric  
17 analysis in pathogenicity tests 1 and 2, but data for pathogenicity test 3 had to be  
18 square root-transformed to meet assumptions of equal variance. Based on the  
19 ANOVAs, significant differences in disease severity were detected 21 dai between  
20 the turnip and mustard plants ( $P = 0.0004$ ,  $P < 0.001$ , and  $P < 0.001$  for tests 1, 2, and  
21 3, respectively). The turnip plants developed more severe symptoms ( $100$ ,  $99.7 \pm$   
22  $0.3$ , and  $84.1 \pm 3.8\%$  of the leaf area with symptom severity in tests 1, 2, and 3,  
23 respectively) than the mustard plants ( $84.8 \pm 3.7$ ,  $77.0 \pm 4.0$ , and  $21.5 \pm 2.9\%$   
24 severity, respectively). In addition, turnip plants developed symptoms earlier than  
25 mustard plants, with pale brown streaks on the stems and veinal browning on the

1 leaves that darkened over time. Veinal browning was followed by development of  
2 small (<5 mm diameter), chlorotic leaf spots, that became diffuse and expanded  
3 rapidly, coalescing and covering most of the leaf surface by 21 dai (Figure 24C).  
4 Symptoms were similar but developed more slowly on mustard leaves (3 to 5 days  
5 more slowly). Hyaline, smooth, cylindrical, mostly aseptate and eguttulate conidia  
6 were observed on short, non-branching conidiophores in pale acervuli (Figure 24D)  
7 on symptomatic leaves of plants inoculated with each of the lineage 2 isolates. The  
8 white, subcuticular conidiomata described by Rawlinson *et al.* (1978) and Fitt *et al.*  
9 (1998) as being produced in patches on leaves of plants infected with *P. brassicae* in  
10 the ~~UK and continental Europe~~ EU and UK (Figure 24A and 1B) were not observed  
11 on any of the turnip or mustard plants inoculated with the lineage 2 isolates. Koch's  
12 postulates were completed by re-isolating the fungus from symptomatic leaves of all  
13 inoculated plants of each species. The fungus could not be re-isolated from the  
14 control plants of each species. Sequencing the ITS rDNA and  $\beta$  *tubulin* regions  
15 confirmed that all the re-isolates matched the original lineage 2 isolates (*data not*  
16 *shown*).

17 **Comparative symptomology caused by isolates of the two lineages.** Very  
18 different symptoms were observed on turnip plants of the cv. Hakurei inoculated with  
19 lineage 1 isolates compared with those inoculated with lineage 2 isolate Cyc001. All  
20 10 lineage 1 isolates produced patches of white conidiomata on leaves, that were  
21 first observed 11 dai (Figure 24A and 24B photos taken 14 dai). Patches of white  
22 cConidiomata were not observed on any of the plants inoculated with the lineage 2  
23 isolate. Instead, the conidiomata observed were pale tan to brown acervuli and,  
24 sometimes, black stromatal knots, that developed when leaves infected with the  
25 lineage 2 isolate were incubated on agar plates or in moist chambers (Figure 24D).

1 By 21 dai, leaves with white conidiomata of the lineage 1 isolates had senesced  
2 more rapidly than plants treated with SDW. The general chlorosis that developed on  
3 leaves inoculated with the 10 lineage 1 isolates -differed from the bright yellow  
4 chlorotic spots observed on plants inoculated with the lineage 2 isolate (Figure 24C).

5 In the first pathogenicity test, there were significant differences among  
6 isolates for all three variables measured. For the number of inoculated leaves that  
7 turned necrotic, there was a significant main effect of isolates ( $P < 0.0001$ ). However,  
8 there were no significant differences in the mean number of necrotic inoculated  
9 leaves caused by 9 the 10 of the 11-lineage 1 isolates of *P. brassicae* and the  
10 lineage 2 isolate, Cyc001, by 28 dai (4.50 to 5.75 necrotic leaves/plant,  $P > 0.05$ ;  
11 Supplementary Figure 2A). Only isolate 2016-5 caused fewer necrotic leaves  
12 (4.50/plant) than that caused by lineage 2 isolate Cyc001. The control plants  
13 averaged  $2.50 \pm 0.29$  necrotic leaves/plant, which was less than that of any of the  
14 inoculated plants. In the repeat test, the main effect of isolates was again significant  
15 ( $P < 0.0001$ ). The lineage 2 isolate Cyc001 caused the greatest number of necrotic  
16 leaves ( $4.00 \pm 0.41$ /plant), followed by the lineage 1 isolate 2016-34 ( $2.75 \pm 0.63$   
17 necrotic leaves/plant). Three of the lineage 1 isolates and the control plants all had  
18  $< 1$  necrotic leaf/plant.

19 The main effect of isolates also significantly affected the number of chlorotic  
20 leaves/plant ( $P = 0.012$  in trial 1). Lineage 2 isolate Cyc001 caused the greatest  
21 number of leaves to turn chlorotic by 28 dai ( $1.8 \pm 0.3$  and  $2.5 \pm 0.7$  leaves/plant in  
22 the trials 1 and 2, respectively) (Supplementary Figure 2B). This did not, however,  
23 differ significantly from that caused by four lineage 1 isolates in the first trial and two  
24 lineage 1 isolates in the repeat trial (means separation based on non-parametric  
25 rank analyses). All other lineage 1 isolates caused fewer chlorotic leaves to

1 develop/plant than that caused by lineage 2 isolate Cyc001 in both trials. None of the  
2 control plants developed chlorotic leaves. For the number of leaves with patches of  
3 white conidiomata, the negative control plants and plants inoculated with Cyc001  
4 were excluded from the ANOVA as white conidiomata did not develop on those  
5 plants (Supplementary Figure 2C). Of the 10 lineage 1 isolates of *P. brassicae*  
6 tested, there was a significant effect of isolates ( $P = 0.005$ ). Isolate 2016-26 caused  
7 the greatest number of leaves to produce patches of white conidiomata ( $4.25 \pm 0.63$   
8 leaves/plant), while UK73 caused the fewest leaves to develop white conidiomata  
9 ( $0.50 \pm 0.29$  leaves/plant). The other isolates did not differ significantly. Very similar  
10 results for number of chlorotic leaves/plant and number of leaves with white  
11 conidiomata/plant were observed in the repeat trials (*data not shown*). Koch's  
12 postulates were completed by re-isolating the fungus (confirmed by sequencing)  
13 from foliar lesions of plants inoculated with the lineage 2 isolate or from white  
14 conidiomata that developed on leaves of plants inoculated with the lineage 1  
15 isolates. Fungi were not re-isolated from any of the control plants.

16 **Sexual compatibility testing.** *In vitro* crosses on plates of 3% MEA between  
17 lineage 1 isolates of *P. brassicae* of *MAT1-1* and *MAT1-2* types resulted in mature  
18 apothecia developing for 22 of the 25 crosses (88%) (Table 3). Asci and ascospores  
19 subsequently were confirmed in 19 of these 25 crosses (76%) after nine weeks. By  
20 contrast, attempts at inducing sexual reproduction under similar conditions were  
21 unsuccessful between lineage 2 isolates of opposite *MAT1-1* and *MAT1-2* types, and  
22 between lineage 1 and lineage 2 isolates of opposite *MAT* types. Structures that  
23 appeared to be apothecial initials were observed in some crosses of lineage 1 x  
24 lineage 2 isolates but none of these developed into mature apothecia with

1 ascospores (Table 3). Apothecial initials did not develop in any of the attempted  
2 *MAT1-1* and *MAT1-2* crosses among lineage 2 isolates.

3 **Morphological analyses.** Considerable colony variation was evident among  
4 the 10 lineage 2 isolates of the light leaf spot pathogen, with diverse pigment colours  
5 (black, brown, grey, pink, red, and yellow) (Figure 32A). For all lineage 2 isolates  
6 examined (except Cyc023A), the observed phenotype was consistent among the  
7 three replicate cultures on MEA. Additional comparisons of the 10 lineage 2 isolates  
8 with four representative lineage 1 isolates of *P. brassicae* revealed no obvious  
9 differences in colony phenotype that distinguished isolates from the two major  
10 geographic regions (Figure 32A and 32B).

11 Examination of conidia produced *in vitro* by colonies growing on 3% MEA for  
12 6 weeks revealed it was not possible to distinguish between the 10 lineage 1 and  
13 eight lineage 2 isolates based on shape of the conidia. All 18 isolates produced  
14 hyaline, usually aseptate, and cylindrical conidia. Moreover, there was no significant  
15 difference among the lineage 1 vs. lineage 2 isolates for conidial length [lineage 1  
16 isolates averaged  $8 \pm 0.13$   $\mu\text{m}$  (mean  $\pm$  standard error) for 250 conidia, and lineage  
17 2 isolates averaged  $7.80 \pm 0.12$   $\mu\text{m}$  for 200 conidia; Student's *t* test = 1.23, *df* = 448,  
18 *P* = 0.262] or diameter (lineage 1 isolates averaged  $2.23 \pm 0.03$   $\mu\text{m}$  for 250 conidia,  
19 and lineage 2 isolates averaged  $2.18 \pm 0.03$   $\mu\text{m}$  for 200 conidia; Student's *t* test =  
20 1.11, *df* = 448, *P* = 0.268).

21 In contrast, when conidia were washed directly from symptomatic leaves of  
22 the turnip cv. Hakurei 28 dai of the plants with 10 lineage 1 isolates and 10 lineage 2  
23 isolates, significant differences were observed in morphology of conidia produced by  
24 isolates from the two major geographic regions. A single septum was observed in  
25 some conidia collected from leaves inoculated with most (9 of 10) lineage 2 isolates

1 but only from leaves inoculated with 1 of the 10 lineage 1 isolates. The number of  
2 conidia with a septum averaged  $5.3 \pm 1.1$  for 60 conidia measured/isolate for the 10  
3 lineage 2 isolates compared to  $0.1 \pm 0.1$  for 60 conidia/isolate for the lineage 1  
4 isolates ( $P < 0.0001$ ). Conidial width did not differ significantly ( $P = 0.1300$ ,  $R^2 = 0.39$ )  
5 among all 20 isolates, but was significantly greater for the 10 lineage 1 isolates  
6 (average of  $4.41 \pm 0.02 \mu\text{m}$ ) than for the 10 lineage 2 isolates ( $3.14 \pm 0.17 \mu\text{m}$ ;  $P$   
7  $< 0.0001$ ,  $R^2 = 0.60$ ). Conidial length differed significantly among the 20 isolates ( $P =$   
8  $0.0135$ ,  $R^2 = 0.47$ ), and between the 10 lineage 1 isolates compared to the 10  
9 lineage 2 isolates ( $P < 0.0001$ ,  $R^2 = 0.60$ , respectively). Conidial length averaged  
10  $10.08 \pm 0.07 \mu\text{m}$  for the 10 lineage 2 isolates vs.  $11.70 \pm 0.06 \mu\text{m}$  for the 10 lineage  
11 1 isolates. In summary, the 10 lineage 2 isolates produced slightly shorter and  
12 narrower conidia *in planta* than the 10 lineage 1 isolates, and 90% of the lineage 2  
13 isolates produced a few septate conidia *in planta* whereas only one of the 10 lineage  
14 1 isolates formed septate conidia *in planta*.

15 **Fungicide sensitivity testing and molecular analyses.** *In vitro* testing  
16 showed the six lineage 2 isolates to be very sensitive to carbendazim as no fungal  
17 growth was observed on any of the agar plates amended with  $0.39 \mu\text{g}$   
18 carbendazim/mL (Table 4). This contrasted with lineage 1 isolates of *P. brassicae*  
19 known to be moderately and highly resistant to carbendazim, UK73 and 8CAB,  
20 respectively. Subsequent inspection of the  $\beta$ -tubulin aa sequences from 12 lineage 2  
21 isolates revealed none contained the E198A, E198G, F220Y, or L240F substitutions  
22 that have been associated with MBC resistance in some UK *P. brassicae* isolates  
23 (Carter *et al.* 2013). Additional sensitivity testing revealed the six lineage 2 isolates to  
24 be sensitive to prothioconazole as no fungal growth was observed on agar medium  
25 amended with  $1.56 \mu\text{g/ml}$ , with the exception of one replicate plate of lineage 2

1 isolate Cyc013A, on which a single colony <1 mm in diameter was observed. This  
2 contrasted with the growth observed for UK isolates UK73 and 8CAB, for which EC<sub>50</sub>  
3 values had previously been determined to be  $\geq 1.23$   $\mu\text{g/ml}$  (Carter *et al.* 2014).

5

### Discussion

6 In this study, isolates of the light leaf spot pathogen from three major  
7 geographic regions were resolved into two closely related but genetically distinct  
8 phylogenetic lineages. The first (lineage 1) contained isolates from the UK,  
9 continental Europe, and EU, OC, and UK isolates that originated from *B. napus*, *B.*  
10 *oleracea*, and *B. rapa* plants, and included the type specimen of *P. brassicae*,  
11 IMI81823 (Rawlinson *et al.* 1978) for which only a partial ITS rDNA sequence could  
12 be generated from the herbarium specimen. The second (lineage 2) included NA  
13 isolates that originated from *B. juncea*, *B. napus*, *B. rapa*, and *Raphanus* spp. from  
14 western Oregon and western Washington. The two lineages were distinguished  
15 consistently based on: 1) Bayesian and maximum likelihood analyses of individual  
16 sequences and MLSA of concatenated sequences of the ITS rDNA as well as the  $\beta$ -  
17 *tubulin* and *TEF1- $\alpha$*  genes; 2) phylogenetic analyses of *MAT1-1* and *MAT1-2*  
18 sequences; and 3) rep-PCR DNA fingerprinting (including BOX, ERIC, and GTG<sup>5</sup>  
19 variants). In addition, *MAT1-1* type lineage 2 isolates contained a 99 bp indel in the  
20 *MAT1-1-3* gene that was not present in any of the lineage 1 isolates of *P. brassicae*  
21 examined. The two lineages were discriminated exclusively based on geographic  
22 origin, with no additional subdivision based on original host species.

23 Pathogenicity tests in greenhouse and growth chamber conditions revealed  
24 strikingly different foliar symptoms on *B. rapa* seedlings inoculated with lineage 1 vs.  
25 lineage 2 isolates. All 10 lineage 2 isolates caused bright yellow chlorotic spots, each

1 of which developed a necrotic center and veinal browning. These yellow spots  
2 expanded rapidly, remaining chlorotic and leading to leaf chlorosis and eventual  
3 necrosis of entire inoculated leaves. Pale tan to light brown acervuli formed in the  
4 chlorotic and necrotic leaf tissue, in which conidia were observed when examined  
5 microscopically. In contrast, the 10 lineage 1 isolates resulted in formation of white  
6 conidiomata on otherwise 'healthy' green leaves, followed by rapid leaf necrosis  
7 (sometimes with leaf distortion and crinkling, but never with bright yellow chlorotic  
8 lesions). Overall, these results are consistent with the different symptoms observed  
9 on naturally infected plants under field conditions on the continents from which the  
10 original fungal isolates were obtained (Carmody 2017; Karandeni Dewage *et al.*  
11 2018).

12 Isolates of *MAT1-1* and *MAT1-2* types were found for both lineage 1 and  
13 lineage 2. *In vitro* crosses between lineage 1 isolates of *MAT1-1* and *MAT1-2* types  
14 resulted in development of mature apothecia with asci and ascospores for a majority  
15 of the crosses (76%) within nine weeks of pairing the isolates, which is consistent  
16 with previous studies (Ilott *et al.* 1984). Conversely, mature sexual structures were  
17 not observed in similar crosses between lineage 2 isolates of opposite *MAT* type,  
18 i.e., no sexual cycle could be confirmed. A few of the attempted sexual crosses  
19 between lineage 1 and lineage 2 isolates of opposite *MAT* type did result in what  
20 appeared to be apothecial initials, but these structures did not develop into mature  
21 apothecia with asci and ascospores. One possibility is that the apothecial initials  
22 observed in these inter-lineage crosses could have resulted solely from the lineage 1  
23 isolate, as Ilott *et al.* (1984) reported that some UK isolates produced what appeared  
24 to be apothecial initials even in single-isolate cultures. The inability to confirm  
25 sexual reproduction between the two lineages of opposite mating type might be

1 explained by the sequence divergence observed at the *MAT1-1* locus, i.e., the 99 bp  
2 indel detected in the *MAT1-1* lineage 2 isolates but not in lineage 1 isolates of this  
3 mating type. ~~Further work is now required~~ needed to investigate the possibility of  
4 ~~sexual compatibility between isolates of lineages 1 and 2, and the~~ The present  
5 results of this study should be interpreted with caution, ~~however,~~ given the limited  
6 number of isolates tested and the limited conditions under which the isolates were  
7 tested for sexual compatibility crossing. It is possible that lineage 2 isolates may have  
8 different *in vitro* development requirements for induction of a sexual cycle, given that  
9 no sexual stage has yet been identified in the Pacific Northwest region of the USA  
10 where this pathogen was first detected in NA.

11 The lineage 2 isolates of the light leaf spot pathogen exhibited several  
12 'signatures of sexuality' that are indicative of cryptic sexual potential. First, the ratio  
13 of *MAT1-1*:*MAT1-2* type isolates did not deviate significantly from a 1:1 distribution,  
14 as is typically the case under frequency-dependent selection operating on *MAT*  
15 genes (Milgroom 1996). Second, the lineage 2 isolates exhibited high genotypic  
16 (based on rep-PCR DNA fingerprinting) and phenotypic (based on colony  
17 morphology on 3% MEA) diversity, as is usually observed with sexually outcrossing  
18 populations (McDonald & Linde 2002). The lineage 2 isolates appeared more diverse  
19 (7 of 9 isolates had a unique rep-PCR genotype) than the lineage 1 isolates (3 of 10  
20 isolates had a unique genotype). Further work is required to investigate possible  
21 cryptic sexuality in lineage 2 isolates, including more extensive attempts at sexual  
22 crossing, e.g., *in planta* on senescing host debris (Gilles *et al.* 2001). The presence  
23 of a sexual cycle in lineage 2 could affect pathogen dispersal and, potentially,  
24 increase the risk of breakdown in effectiveness of some disease management  
25 strategies, e.g., from development of fungicide resistance and/or the presence of

1 virulence genes in the pathogen population that overcome host plant resistance  
2 (McDonald & Linde 2002).

3 Morphologically, it was possible to distinguish between conidia of lineage 1  
4 and 2 isolates produced on infected *B. rapa* plants. Lineage 2 isolates produced  
5 slightly shorter and narrower conidia [ $10.08 \pm 0.07$  (mean  $\pm$  standard deviation)  $\times$   
6  $3.14 \pm 0.17 \mu\text{m}$ ] than lineage 1 isolates ( $11.70 \pm 0.06 \mu\text{m} \times 4.41 \pm 0.02 \mu\text{m}$ ). In  
7 addition, a limited number of conidia produced by lineage 2 isolates formed a single  
8 septum as the conidia aged, whereas only a single isolate of lineage 1 (of the 10  
9 examined) occasionally produced conidia that developed a septum. By contrast, no  
10 differences in conidial dimensions or colony colour were observed between the  
11 lineage 1 and 2 isolates when grown on 3% MEA. Isolates from both lineages  
12 formed a range of black, brown, grey, pink, or yellow pigmentation on this medium.

13 The difference in spore dimensions observed for spores of lineages 1 and 2  
14 generated *in vitro* vs. *in vivo* could reflect the well-documented potential impact of  
15 substrate (3% MEA vs. live plants in this case) on spore production by many fungi.  
16 However, the measurement of spores produced *in vitro* was done at Rothamsted  
17 Research whereas the measurement of spores produced *in vivo* was done at WSU,  
18 which confounded any potential effects of the location and method with differences in  
19 spore dimensions among isolates. Given these difficulties with morphological  
20 discrimination *in vitro* between isolates of the two lineages, specific PCR assays  
21 have since been designed by King and West at Rothamsted to enable rapid lineage  
22 discrimination (*data not shown*). Such PCR assays could be used to differentiate  
23 isolates of the two lineages, including isolates of the two lineages present in infected  
24 leaves, seed, etc.

1 The first report of light leaf spot in NA was in Oregon in 2014, with subsequent  
2 widespread distribution of the disease discovered across western Oregon and, more  
3 recently, in three counties in Washington State, which suggests fairly rapid spread of  
4 the causal agent within the Pacific Northwest USA. Indeed, based on the lineage 2  
5 isolates evaluated in this study, the pathogen was confirmed as far north as  
6 Whatcom Co., WA and as far south as Douglas Co., OR. The geographic origin of  
7 lineage 2 isolates in the USA remains unclear. However, based on this study,  
8 lineage 2 isolates appear not to have originated from the UK, continental Europe, or  
9 EU, OC, or the UK as isolates from those regions were in the genetically distinct  
10 lineage 1. One possible source of lineage 2 isolates is Asia. Light leaf spot outbreaks  
11 have been reported in Japan and Thailand (CABI 2015; Rawlinson *et al.* 1978).  
12 Future work to characterize Asian isolates should provide insight on a more global  
13 scale of the potential origin of the NA isolates.

14 Currently, the two lineages appear to be restricted geographically to either the  
15 UK, continental Europe, and OC ~~the EU, OC, and UK~~ (lineage 1) or to NA (lineage  
16 2). Therefore, appropriate precautions are needed to prevent movement of isolates  
17 from the different lineages between se-regions and to other parts of the world. This  
18 includes transfer of potentially infected plants or seed (Carmody & du Toit 2017) on  
19 which the pathogen might be present symptomatically or asymptotically. More  
20 comprehensive testing of the responses of *B. napus*, *B. oleracea*, *B. rapa* and other  
21 Brassicaceae germplasm to isolates from the two lineages is needed to assess  
22 potential differences in susceptibility of plant germplasm (Boys *et al.* 2012). Although  
23 this study indicated that isolates from lineages 1 and 2 are sexually incompatible,  
24 there remains a risk of hybridization or somatic recombination between isolates of  
25 the two groups. Given the recent rapid spread of lineage 2 across western Oregon

1 and western Washington, there is also a risk of spread into Canada, the world's third  
2 largest producer of canola (*B. napus*), and other regions of the USA as well as  
3 Mexico.

4 Management of light leaf spot in the ~~UK and continental Europe~~ ~~EU and UK~~ is  
5 based primarily on timely applications of efficacious fungicides. Prior to this study,  
6 data were not available on the sensitivity of lineage 2 isolates of the light leaf spot  
7 pathogen to fungicides used to control this disease in the ~~UK and continental~~  
8 ~~Europe. EU and UK~~. Phenotypic screening of six lineage 2 isolates revealed all to be  
9 sensitive to both carbendazim and prothioconazole. Examination of the  $\beta$ -tubulin aa  
10 sequences of lineage 2 isolates revealed 100% identity to that of a UK isolate  
11 previously classified as sensitive to MBC fungicides (KC342227; Carter *et al.* 2013),  
12 with no evidence for the key substitutions (e.g., E198A or L240F) that have been  
13 correlated with MBC resistance in lineage 1 isolates (Carter *et al.* 2013). Although  
14 more isolates should be tested, it appears likely that lineage 2 isolates might be  
15 controlled effectively with applications of MBC and DMI fungicides, as demonstrated  
16 recently with MBC and DMI fungicide seed treatments evaluated with a mustard  
17 seed lot infected with a lineage 2 isolate (Carmody & du Toit 2017). However, given  
18 the emergence of resistance to both fungicide groups in some lineage 1 isolates  
19 (Carter *et al.* 2013; 2014), implementation of fungicide resistance management  
20 strategies by NA brassica growers will be important to extend the effective life of  
21 these fungicides against the pathogen (e.g., using mixtures or rotations of fungicides  
22 with different modes of action).

23 In conclusion, based on the CSC that combines morphological, ecological,  
24 biological, and genetic (phylogenetic) data (Crous *et al.* 2015), convincing evidence  
25 was generated in this study for two genetically distinct evolutionary lineages of *P.*

1 *brassicae*, with lineage 1 comprising isolates from the [UK, continental Europe, and](#)  
2 [OC, EU, OC, and UK](#) and including the type specimen, IMI81823 (Rawlinson *et al.*  
3 1978); and lineage 2 comprising NA isolates. More detailed morphological, genetic,  
4 and biological assessment of a broader collection of isolates from additional  
5 geographic locations and other *Pyrenopeziza* species should enable determination  
6 of whether the NA isolates represent a new species. Furthermore, given distinct  
7 differences in symptoms [and signs \(types of conidiomata\)](#) observed on *B. rapa* and  
8 *B. juncea* plants inoculated with isolates of the two lineages, [and also disease](#)  
9 [symptoms observed on both inoculated and naturally infected plants/hosts of \(e.g. \*B.\*](#)  
10 [juncea, \*B. napus\*, \*B. oleracea\*, \*B. rapa\*, and \*Raphanus sativus\* \(Carmody 2017;](#)  
11 [Claassen 2016\)](#), we propose the common name, 'chlorotic leaf spot', be used to  
12 describe the disease caused by lineage 2 isolates in order to differentiate this  
13 disease from classic light leaf spot symptoms caused by isolates of lineage 1 of *P.*  
14 *brassicae*.

## 1 **Figure legends**

2 [Figure 1. Phylogenetic trees from Bayesian analysis of multiple gene sequences](#)  
3 [obtained from \*Pyrenopeziza brassicae\* isolates from the United Kingdom \(UK\),](#)  
4 [continental Europe \(EU\), North America \(NA\), and Oceania \(OC\) as well as other](#)  
5 [fungal genera and species. Trees were constructed with partial sequences from \(a\)](#)  
6 [the internal transcribed spacer \(ITS\) region of ribosomal DNA \(rDNA\), \(b\) the  \$\beta\$ -](#)  
7 [tubulin gene, \(c\) the translation elongation factor \(\*TEF\*\) 1- \$\alpha\$  gene, and \(d\) the](#)  
8 [concatenated sequences from all three regions. Bayesian posterior probabilities are](#)  
9 [indicated at the nodes \(BPP\). The outgroup sequence used for each analysis was](#)  
10 [from \*Botryosphaeria dothidea\*. Refer to Table 1 and Supplementary Table 1 for](#)  
11 [details of the isolates and sequences.](#)

12  
13 [Figure 24. Light leaf spot signs \(patches of white conidiomata\) produced by isolates](#)  
14 [2016-26 of \*Pyrenopeziza brassicae\* from the United Kingdom and continental](#)  
15 [European-European Union and United Kingdom isolates \(lineage 1\), of \*Pyrenopeziza\*](#)  
16 [brassicae](#) 14 days after inoculation (dai) of 'Hakurei' turnip (*Brassica rapa*) plants (a  
17 and b). Close-up image of white conidiomata produced by [2016-26](#), a lineage 1  
18 isolate of *P. brassicae* on a turnip leaf (b). Symptoms of light leaf spot caused by  
19 isolate Cyc001 (lineage 2) of *P. brassicae* from Benton Co., Willamette Valley,  
20 Oregon, USA- [21 dai](#), were typical of those observed for other isolates collected in  
21 Washington and Oregon, i.e., coalescing chlorotic spots and veinal browning without  
22 any white conidiomata (c). Typical pale tan to brown, circular acervuli and black  
23 stomatal knots observed on turnip leaves infected with [Cyc001](#), a lineage 2 North  
24 American isolate, ~~after and incubating the leaf section on V8 agar medium on a~~  
25 [lab bench at room temperature for approximately 7 days](#) (d).

1

2 Figure 32. Variation in colony morphology of isolates of *Pyrenopeziza brassicae*  
3 associated with brassica light leaf spot that were grown on 3% malt extract agar for  
4 four months. (a) Ten North American (NA) isolates of lineage 2 (three replicates of  
5 each shown); note the phenotypic variation among isolates, which was consistent  
6 among replicate plates with the exception of Cyc023A. (b) Four United Kingdom and  
7 continental European European (EU) and United Kingdom (UK) isolates of lineage 1  
8 of *P. brassicae* showing overlapping colony morphology with that of NA isolates.  
9 Isolates from NA, the UK, and continental European (EU), EU, and UK isolates could  
10 not be distinguished based on colony appearance.

11

12 Figure 3. Phylogenetic trees from Bayesian analysis of multiple gene sequences  
13 obtained from *Pyrenopeziza brassicae* isolates from the United Kingdom (UK),  
14 continental Europe-European Union (EU), United Kingdom (UK), North America  
15 (NA), and Oceania (OC) as well as other fungal genera and species. Trees were  
16 constructed with partial sequences from (a) the internal transcribed spacer (ITS)  
17 region of ribosomal DNA (rDNA), (b) the  $\beta$ -tubulin gene, (c) the *translation elongation*  
18 *factor (TEF) 1- $\alpha$*  gene, and (d) the concatenated sequences from all three regions.  
19 Bayesian posterior probabilities are indicated at the nodes (BPP). The outgroup  
20 sequence used for each analysis was from *Botryosphaeria dothidea*. Refer to Table  
21 1 and Supplementary Table 1 for details of the isolates and sequences.

22

23 Figure 4. Rep-PCR DNA fingerprinting of 19 isolates of *Pyrenopeziza brassicae*  
24 associated with brassica light leaf spots on brassicas. Three variants of the rep-PCR

1 [assay](#) were used: (a) BOX PCR, (b) GTG<sup>5</sup> PCR, and (c) ERIC PCR. The isolates in  
2 lanes 1 to 19 are: PB12, 8CAB, E3A, UK73, a UK field isolate, 17KALE02, 2016-09,  
3 2016-34, 2016-50, CBS157.35, Cyc013A, Cyc015, Cyc017, Cyc025, 14CC2,  
4 14CC4A, 14CC6, 14CC8A, 15LS13B (see Table 1 for isolate details). Geographic  
5 origin of the isolates (EU/OC = [continental Europe, UK, and Oceania](#)an-Union, NA =  
6 North America; [OC = Oceania, UK = United Kingdom](#)) is noted at the base. Lanes 1  
7 – 10 = lineage 1 isolates, lanes 11 – 19 = lineage 2 isolates, lane 'L' = Hyperladder 1  
8 (Bioline), and lane 'W' = no-template water (control) sample. [Differences](#) between  
9 the two groups of isolates [based on DNA fingerprint bands](#) are indicated with white  
10 arrowheads.

11  
12 Supplementary Figure 1. Phylogenetic trees based on maximum likelihood analyses  
13 of multiple gene sequences obtained from *Pyrenopeziza brassicae* isolates from the  
14 [United Kingdom \(UK\)](#), [continental Europe \(EU\)](#), North America ([NA](#)), and Oceania  
15 ([OC](#)) as well as other fungal genera and species. Trees were constructed with partial  
16 sequences from (a) the internal transcribed spacer (ITS) region of ribosomal DNA  
17 (rDNA), (b) the *β-tubulin* gene, (c) the *translation elongation factor (TEF) 1-α* gene,  
18 and (d) the concatenated sequences from all three regions. The consensus trees  
19 shown are based on 1,000 bootstrap replicates with only support values >70%  
20 shown for clarity. Analyses were rooted using *Botryosphaeria dothidea* sequences.  
21 Refer to Table 1 and Supplementary Table 1 for details of the isolates and  
22 sequences.

23  
24 [Supplementary Figure 2. Results of a pathogenicity test of isolates of \*Pyrenopeziza\*](#)  
25 [brassicae from continental Europe and the United Kingdom \(UK\) on 'Hakurei' turnip](#)

1 (*Brassica rapa*) compared to North American isolate Cyc001. Plants treated with  
2 water served as a control treatment. Ratings were done 28 days after inoculation,  
3 including the number of necrotic leaves (a), number of chlorotic leaves (b), and  
4 number of leaves that developed white conidiomata of *P. brassicae* (c). Each bar  
5 represents the mean  $\pm$  standard error of four replicate plants. Means with different  
6 letters are significantly different based on Fisher's protected least significant  
7 difference at  $P < 0.05$ . Data were rank-transformed although original means are  
8 shown. The control treatment was removed from the analysis for number of chlorotic  
9 leaves and number of leaves with white conidiomata as none of the leaves of those  
10 plants was chlorotic or developed white conidiomata. Results of the repeat trial were  
11 similar (*data not shown*), as detailed in the main text.

TABLE 1. Isolate accession numbers and herbarium accession numbers for infected turnip leaves submitted to the Westerdijk Fungal Biodiversity Institute (WFBI), International Mycological Institute (IMI) isolate accession numbers, and GenBank DNA sequence accession numbers for isolates of *Pyrenopeziza* associated with light leaf spot of brassicas in [the United Kingdom](#), [continental Europe](#) ~~the European Union~~, Oceania, ~~(Australia and New Zealand)~~, ~~United Kingdom~~, and North America that were evaluated in this study.

| Continent / isolate code (lineage)  | Isolate origin          | Year collected | Original host                              |                        | Original collector | WFBI herbarium accession no. | WFBI live culture accession no. | IMI live culture accession no. | GenBank accession no. of DNA region or gene <sup>aa</sup> |                  |               |          |  |  |

<sup>a</sup> ITS rDNA = internal transcribed spacer (ITS) region of ribosomal DNA (rDNA);  $\beta$ -tubulin = beta-tubulin gene; *TEF1- $\alpha$*  = translation elongation factor 1- $\alpha$

gene; *MAT* = mating type genes of the light leaf spot pathogen (Ilott *et al.* 1984; Foster *et al.* 2002). [All sequences with accession numbers in this table were generated in this study.](#)

<sup>b</sup> Isolates confirmed as *MAT1-1* or *MAT1-2* type using the multiplex [PCR assays](#) of Foster *et al.* (2001). [All mating type sequences with accession numbers in this table were generated as part of this study.](#)

<sup>bc</sup> S = isolates from continental Europe and UK (n = 10) inoculated onto *Brassica rapa* cv. Hakurei to compare symptomology with that caused by North American isolate Cyc001, as detailed in the main text. M = isolates from continental Europe and UK (n = 4) compared with isolates from North America (n = 10) for morphology on malt extract agar, as detailed in the main text. CO = isolates used to compare conidial morphology *in vitro* and *in vivo*, as detailed I in the main text.

<sup>ed</sup> DNA extracted from conidia washed from an infected *B. rapa* leaf as detailed in the main text.

<sup>d\_e</sup> Type specimen of *P. brassicae* examined in the form of apothecia in dried culture (Rawlinson *et al.* 1978). Only a partial ITS rDNA sequence (MN028386) could be amplified from the herbarium specimen.

TABLE 2. Primers used in polymerase chain reaction (PCR) assays to amplify the internal transcribed spacer (ITS) ribosomal DNA (rDNA) region,  $\beta$ -tubulin gene, *TEF1- $\alpha$*  gene, *MAT1-1-3* gene, and *MAT1-2-1* gene of [isolates of \*Pyrenopeziza\* from the European Union \(EU\)](#), United Kingdom (UK), [continental European](#), Oceania, [\(OC\)](#), and North America [that were n \(NA\) isolates of \*Pyrenopeziza\*](#) associated with light leaf spot of brassicas, for phylogenetic comparisons of isolates from these geographic regions.<sup>a</sup>

<sup>a</sup> Isolates were confirmed as either *MAT1-1* or *MAT1-2* types using the multiplex PCR assays of Foster *et al.* (2002).

<sup>ab</sup> Three replicate pairings were established for each attempted sexual cross. The superscript number denotes the number of replicate plates on which apothecial initials (Ai), apothecia (Ap), or asci and ascospores (As) were observed. '-' indicates no sexual structures were observed. Results shown were after the isolates had been paired on 3% malt extract agar for nine weeks. Refer to Table 1 for details of each isolate.

<sup>b</sup> Isolates were confirmed as either *MAT1-1* or *MAT1-2* types using the multiplex PCR assay of Foster *et al.* (2002).

<sup>a</sup> Isolates were grown for 18 days in the dark on 3% malt extract agar plates that contained either no fungicide, 0.39 µg carbendazim/mL, or 1.56 µg

prothioconazole/mL. [Each All isolates were](#) tested in triplicate for each treatment. Results were scored as follows: '+' = large colonies visible (>1 cm

diameter); '-' = no colony of any size visible; 'P' = multiple pinhead colonies (each ≤1 mm diameter) visible; 'p' = a single pinhead colony (≤1 mm diameter)

visible.

<sup>b</sup> Reference isolates previously characterized as sensitive (FR2), moderately resistant (UK73), or resistant (8CAB) to carbendazim. EC<sub>50</sub> values for sensitivity of these reference isolates to prothioconazole had previously been determined to be 0.14 (FR2), 1.23 (UK73), and 3.00 (8CAB) µg/mL (Carter *et al.* 2013).

<sup>a</sup> ITS rDNA = internal transcribed spacer (ITS) region of ribosomal DNA (rDNA);  $\beta$ -tubulin = beta-tubulin gene; *TEF1- $\alpha$*  = translation elongation factor 1- $\alpha$

gene. Only a partial ITS1 rDNA sequence could be amplified from the type herbarium specimen of *P. brassicae* (IMI81823), and was deposited in GenBank as Accession MN028386. Underlined sequences were used for the concatenated analyses of all three loci.

<sup>b</sup> *Botryosphaeria dothidea* genome available at [https://genome.jgi.doe.gov/Botdo1\\_1/Botdo1\\_1.home.html](https://genome.jgi.doe.gov/Botdo1_1/Botdo1_1.home.html) (accessed 21 May 2019).

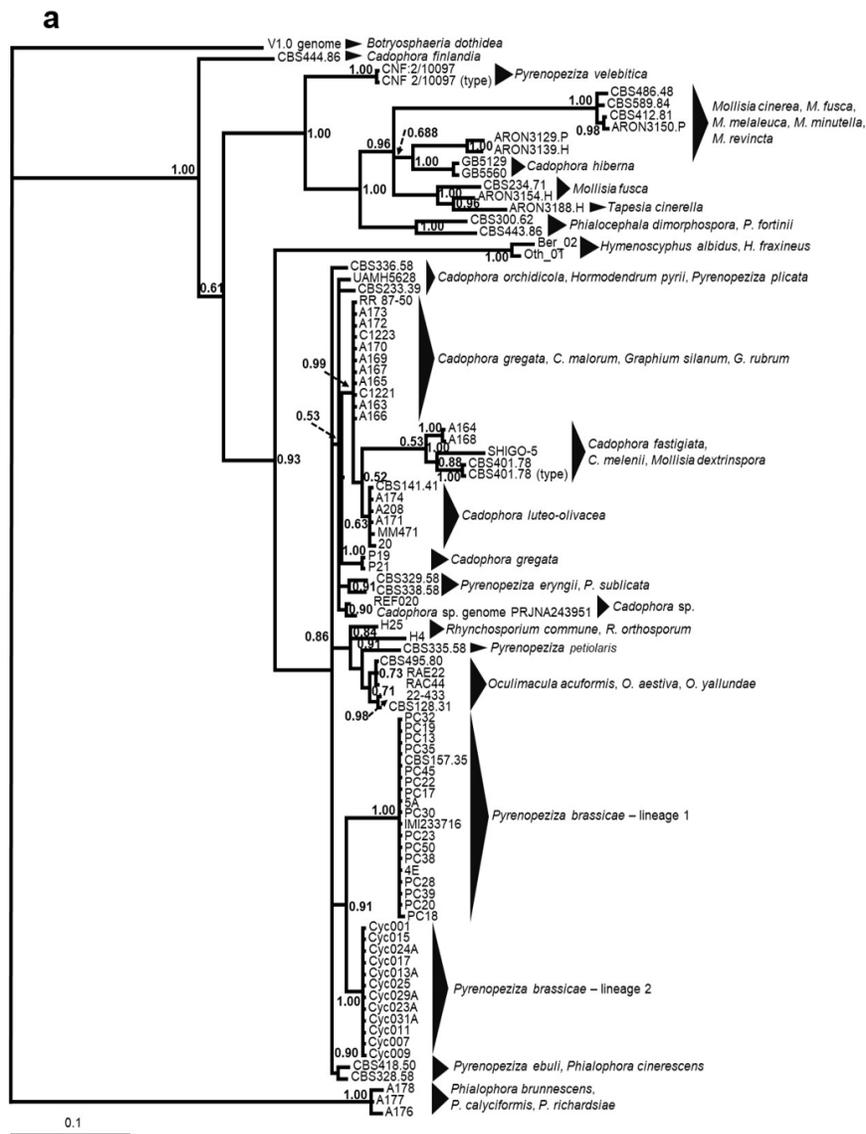

Figure 1. Phylogenetic trees from Bayesian analysis of multiple gene sequences obtained from *Pyrenopeziza brassicae* isolates from the United Kingdom (UK), continental Europe (EU), North America (NA), and Oceania (OC) as well as other fungal genera and species. Trees were constructed with partial sequences from (a) the internal transcribed spacer (ITS) region of ribosomal DNA (rDNA), (b) the  $\beta$ -tubulin gene, (c) the *translation elongation factor (TEF) 1-a* gene, and (d) the concatenated sequences from all three regions. Bayesian posterior probabilities are indicated at the nodes (BPP). The outgroup sequence used for each analysis was from *Botryosphaeria dothidea*. Refer to Table 1 and Supplementary Table 1 for details of the isolates and sequences.

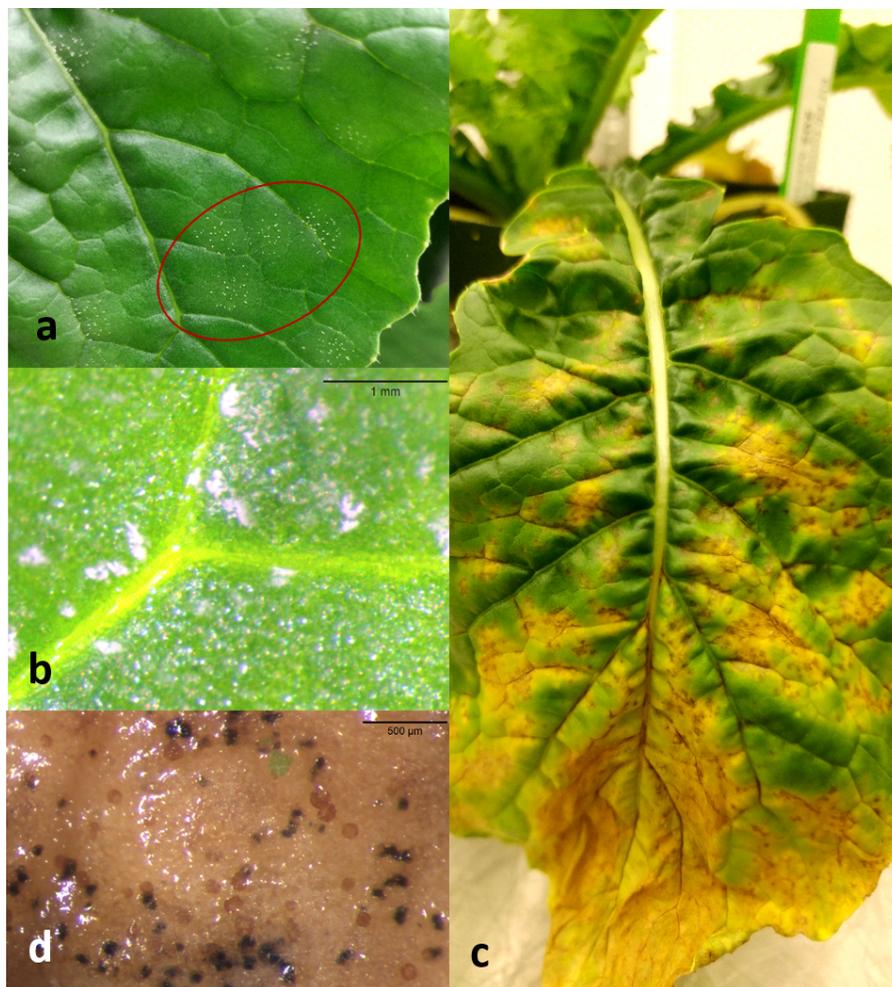

Figure 2. Light leaf spot signs (patches of white conidiomata) produced by isolate 2016-26 of *Pyrenopeziza brassicae* from the United Kingdom (lineage 1), 14 days after inoculation (dai) of 'Hakurei' turnip (*Brassica rapa*) plants (a and b). Close-up image of white conidiomata produced by 2016-26, a lineage 1 isolate of *P. brassicae* on a turnip leaf (b). Symptoms of light leaf spot caused by isolate Cyc001 (lineage 2) of *P. brassicae* from Benton Co., Willamette Valley, Oregon, USA 21 dai, were typical of those observed for other isolates collected in Washington and Oregon, i.e., coalescing chlorotic spots and veinal browning without any white conidiomata (c). Typical pale tan to brown, circular acervuli and black stromatal knots observed on turnip leaves infected with Cyc001, a lineage 2 North American isolate, after incubating the leaf section on V8 agar medium on a lab bench at room temperature for approximately 7 days (d).

179x198mm (150 x 150 DPI)

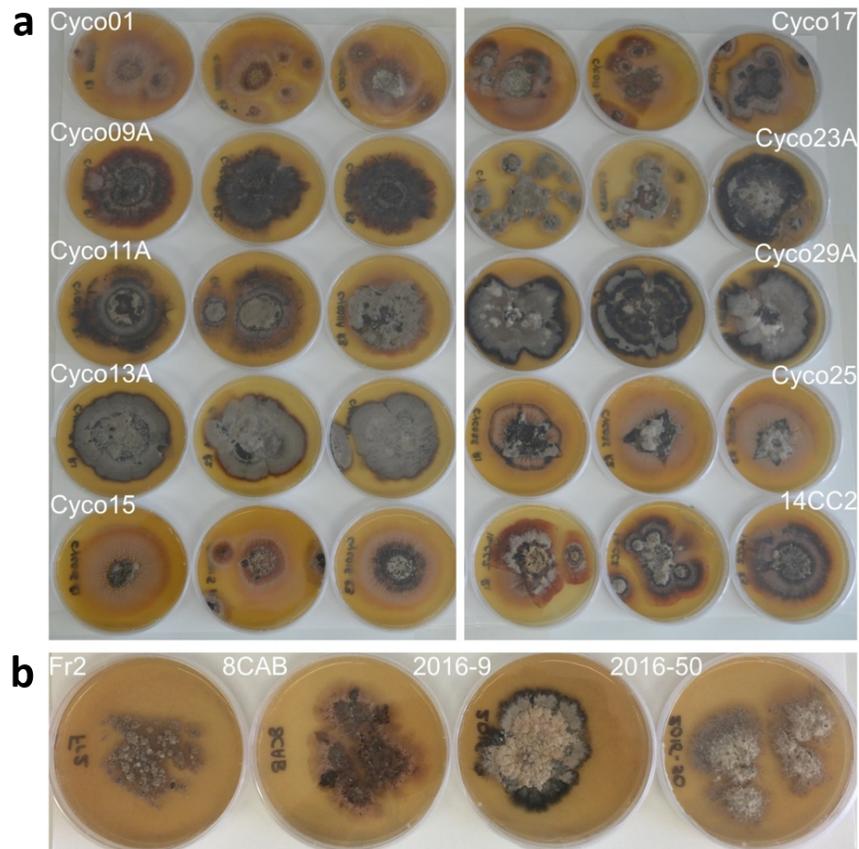

Figure 3. Variation in colony morphology of isolates of *Pyrenopeziza brassicae* associated with brassica light leaf spot that were grown on 3% malt extract agar for four months. (a) Ten North American (NA) isolates of lineage 2 (three replicates of each shown); note the phenotypic variation among isolates, which was consistent among replicate plates with the exception of Cyc023A. (b) Four United Kingdom and continental European isolates of lineage 1 of *P. brassicae* showing overlapping colony morphology with that of NA isolates. Isolates from NA, the UK, and continental Europe (EU) could not be distinguished based on colony appearance.

182x178mm (150 x 150 DPI)

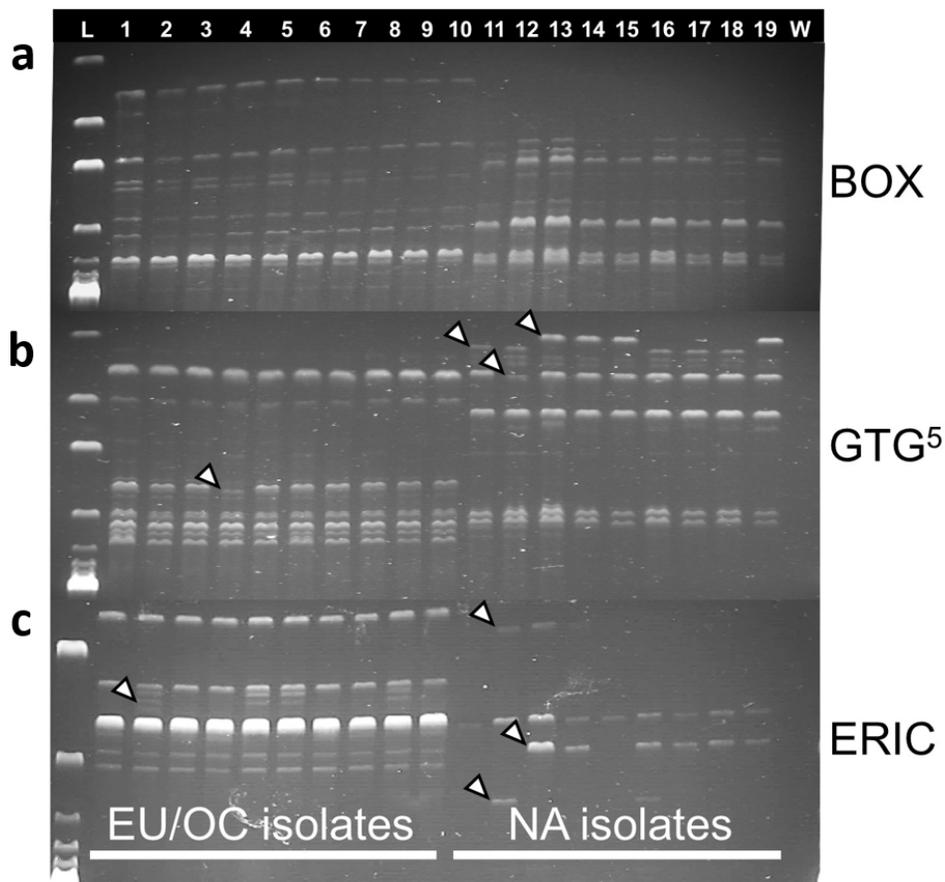

Figure 4. Rep-PCR DNA fingerprinting of 19 isolates of *Pyrenopeziza brassicae* associated with brassica light leaf spot. Three variants of the rep-PCR assay were used: (a) BOX PCR, (b) GTG5 PCR, and (c) ERIC PCR. The isolates in lanes 1 to 19 are: PB12, 8CAB, E3A, UK73, a UK field isolate, 17KALE02, 2016-09, 2016-34, 2016-50, CBS157.35, Cyc013A, Cyc015, Cyc017, Cyc025, 14CC2, 14CC4A, 14CC6, 14CC8A, 15LS13B (see Table 1 for isolate details). Geographic origin of the isolates (EU/OC = continental Europe, UK, and Oceania; NA = North America) is noted at the base. Lanes 1 – 10 = lineage 1 isolates, lanes 11 – 19 = lineage 2 isolates, lane 'L' = Hyperladder 1 (Bioline), and lane 'W' = no-template water (control) sample. Differences between the two groups of isolates based on fingerprint bands are indicated with white arrowheads.
